Panel data models: quick repetition

## LSDV regression

In the model  $y_{it} = \boldsymbol{x}_{it}\boldsymbol{\beta} + \mu_i + u_{it}$ ,

 $\mu_i$  are usually regarded as unobservable variables.

This approach gives appropriate interpretation of  $\beta$ .

Traditional (old) approaches to fixed effects estimation view the  $\mu_i$  as parameters to be estimated along with  $\beta$ .

How to estimate  $\mu_i$  values along with  $\beta$ ?

- ullet Define N dummy variables one for each cross-section.
- Convenient LSDV model expansion: use interactions to control for individual slopes for chosen regressors.

## FD estimator

We can eliminate unobserved individual heterogeneity from the regression:  $y_{it} = \mathbf{x}_{it}\boldsymbol{\beta} + \mu_i + u_{it}$  by first differences (FD) transformation:

$$\Delta y_{it} = y_{it} - y_{i,t-1} = \Delta x_{it} \beta + \Delta \mu_i + \Delta u_{it} = \Delta x_{it} \beta + \Delta u_{it}$$

- ✓ Removes any unobserved heterogeneity.
- $\times$  We remove all time-invariant factors in  $\boldsymbol{x}$ . If the time-invariant regressors are of no interest, this is a robust estimator.

Estimation can be done with FGLS (autocorrelation of transformed residuals), or OLS with HAC robust errors.

FD is most suitable when we have t=1;2 – two period panel (FD may be used with more time periods, we have N(T-1) observations after differencing)

## FD estimator – assumptions

- **FD.1** Functional form:  $y_{it} = \beta_1 x_{it1} + \dots + \beta_k x_{itk} + \mu_i + u_{it}, i = 1, \dots, N, t = 1, \dots, T$
- **FD.2** We have random sample from cross-sectional units.
- **FD.3** Each regressor changes in time at least for some i and no perfect linear combination exists among regressors.
- **FD.4** For each i and t,  $E(u_{it} \mid X_i, \mu_i) = 0$ . [Alt.: regressors are strictly exogenous conditional on unobserved effects:  $corr(x_{iti}, u_{is} \mid \mu_i) = 0$ ,  $\forall t, s$ ]
- **FD.5** Variance of differenced errors conditional on all regressors is constant:  $var(\Delta u_{it} \mid \mathbf{X}_i) = \sigma^2, \quad t = 2, 3, \dots, T.$  [homoskedasticity]
- **FD.6** No serial correlation exists among differenced errors.  $cov(\Delta u_{it}, \Delta u_{is} \mid \mathbf{X}_i) = 0, \quad t \neq s$
- FD.7 Differenced errors are normally distributed conditional on all regressors  $X_i$ .

## FD estimator – assumptions

#### Under **FD.1** - **FD.4**

FD estimator is unbiased.

FD estimator is consistent for fixed T as  $N \to \infty$ .

For unbiasedness,  $E(\Delta u_{it} \mid \mathbf{X}_i) = 0$  (for t = 2, 3, ...) is sufficient (instead of FD.4)

#### Under FD.1 - FD.6

FD estimator is BLUE (conditional on explanatory variables).

Asymptotic inference for FD estimator holds (t and F statistics asymptotically follow corresponding distributions).

#### Under **FD.1** - **FD.7**

FD estimator is BLUE (conditional on explanatory variables).

FD estimators - i.e. pooled OLS on first differences - are normally distributed (t and F statistics have exact t and F distributions).

#### FD estimator

#### Problems related to the FD estimator:

- First-differenced estimates will be imprecise if explanatory variables vary only to a small extent over time (no estimate possible if regressors are time-invariant).
- Potentially, there is insufficient (lower) variability in differenced variables.
- Without strict exogeneity of regressors (e.g. in the case of a lagged dependent variable /say,  $y_{i,t-1}$ / among regressors or with measurement errors), adding further periods does not reduce inconsistency.
- FD estimator may be worse than pooled OLS if explanatory variables are subject to measurement errors (errors in variables EIV).

#### FE estimator

"Fixed" means correlation of  $\mu_i$  and  $x_{it}$ , not that  $\mu_i$  is non-stochastic.

We can rewrite 
$$y_{it} = \mathbf{x}_{it}\boldsymbol{\beta} + \mu_i + u_{it}$$
 as follows:  
 $y_{it} = \beta_1 x_{it1} + \dots + \beta_k x_{itk} + \mu_i + u_{it}, \qquad i = 1, \dots, N, \ t = 1, \dots, T$ 

Now, for each i, we average the above equation over time:

$$\overline{y}_i = \beta_1 \overline{x}_{i1} + \dots + \beta_k \overline{x}_{ik} + \overline{\mu}_i + \overline{u}_i$$

(N equations with individual averages) By subtracting individual

averages from the original observations (time-demeaning), we get:  $\Rightarrow [y_{it} - \overline{y}_i] = \beta_1[x_{it1} - \overline{x}_{i1}] + \dots + \beta_k[x_{itk} - \overline{x}_{ik}] + [u_{it} - \overline{u}_i]$ 

Alternative notation: 
$$\ddot{y}_{it} = \ddot{\boldsymbol{x}}_{it}\boldsymbol{\beta} + \ddot{u}_{it}$$
; where  $\ddot{y}_{it} = y_{it} - \overline{y}_i$ , etc.

FE estimator, denoted  $\hat{\beta}_{FE}$ , is the pooled OLS estimator applied to time-demeaned data.

#### FE estimator

**FE estimator:** by time demeaning, we get rid of the  $\mu_i$  element - as it does not vary over time

- $\mu_i = \overline{\mu}_i \rightarrow \mu_i \overline{\mu}_i = 0$
- Intercept and all time-invariant regressors are also eliminated using the FE (within) transformation.

After FE estimation,  $\mu_i$  elements may be estimated as follows:  $\hat{\mu}_i = \overline{\psi}_i - \hat{\beta}_1 \overline{x}_{i1} - \cdots - \hat{\beta}_k \overline{x}_{ik}, i = 1, \dots, N$ 

However, in most practical applications,  $\mu_i$  values bear limited useful information.

For each C-S observation i, we loose one d.f. in estimation ... for each i, the demeaned errors  $\ddot{u}_{it}$  add up to zero when summed over time. Hence df = N(T-1) - k

## FE estimator – assumptions

- **FE.1** Functional form:  $y_{it} = \beta_1 x_{it1} + \dots + \beta_k x_{itk} + \mu_i + u_{it}$ ,  $i = 1, \dots, N, t = 1, \dots, T$
- **FE.2** We have random sample from cross-sectional units.
- **FE.3** Each regressor changes in time at least for some i and no perfect linear combination exists among regressors.
- **FE.4** For each i and t,  $E(u_{it} \mid \mathbf{X}_i, \mu_i) = 0$ . [Alt.: regressors are strictly exogenous conditional on unobserved effects:  $corr(x_{itj}, u_{is} \mid \mu_i) = 0$ ,  $\forall t, s$ ]
- **FE.5** Variance of errors conditional on all regressors is constant:  $var(u_{it} \mid \boldsymbol{X}_i, \mu_i) = var(u_{it}) = \sigma_u^2, \quad t = 1, 2, ..., T.$  [homoskedasticity]
- **FE.6** No serial correlation exists among idiosyncratic errors.  $cov(u_{it}, u_{is} \mid \mathbf{X}_i, \mu_i) = 0, \quad t \neq s$
- **FE.7** Errors are normally distributed conditional on all regressors  $(X_i, \mu_i)$ .

## FE estimator – assumptions

Under FE.1 - FE.4 (identical to FD.1 - FD.4)

FE estimator is unbiased.

FE estimator is consistent for fixed T as  $N \to \infty$ .

Under **FE.1** - **FE.6** 

FE estimator is BLUE.

FD is unbiased

...**FE.6** makes FE better (less variance) than FD.

Asymptotically valid inference for FE estimator holds (t and F).

Under **FE.1** - **FE.7** 

FE estimator is BLUE and t and F statistics have exact t and F distributions.

FE estimators - i.e. pooled OLS on time demeaned data - are normally distributed.

#### FE vs FD estimator

- For T=2, FE and FD estimators produce identical estimates and inference. (FE must include a time dummy for the second period to be actually identical to the FD estimation output)
- For T>2, FE and FD are both unbiased under FE.1 FE.4. Both FE and FD are consistent for fixed T as  $N\to\infty$
- If  $u_{it}$  is not serially correlated, FE is more efficient than FD
- If  $u_{it}$  follows a random walk (hence  $\Delta u_{it}$  is serially uncorrelated) FD is better than FE.
- If  $u_{it}$  shows some level of positive serial correlation (not a random walk), FD and FE may not be easily compared. For negative correlation of  $u_{it}$ , we prefer FE.

#### RE estimator

If  $\mu_i$  are uncorrelated with  $\boldsymbol{x}_{it}$ , then it may be appropriate to model the individual constant terms as randomly distributed across cross-sectional units (appropriate if C-S units are from a large sample).

- RE models reduce the number of parameters estimated.
- RE estimator is potentially inconsistent, if assumption not met.
- $y_{it} = x_{it}\beta + \mu_i + u_{it}$
- If we can assume that  $\mu_i$  is uncorrelated with each explanatory variable:  $cov(\boldsymbol{x}_{it}, \mu_i) = 0$ ; t = 1, 2, ..., T then we may drop  $\mu_i$  from the equation and  $\beta_j$  estimates will remain unbiased.
- By dropping  $\mu_i$  from the regression, we effectively create a new error term:  $v_{it} = \mu_i + u_{it}$
- As  $\mu_i$  is time-invariant, the random element  $v_{it}$  contains a lot of "inertia", i.e. autocorrelation (unless  $\mu_i = 0$ ).

## RE estimator - FGLS

$$y_{it} = \beta_0 + \beta_1 x_{it1} + \dots + \beta_k x_{itk} + v_{it};$$

The quasi-demeaning (quasi-differencing) parameter  $\lambda$  is used for the FGLS estimation:

$$\theta = 1 - \left[\sigma_u^2/(\sigma_u^2 + T\sigma_\mu^2)\right]^{1/2}, \quad 0 \le \theta \le 1$$
 where  $var(\mu_i) = \sigma_\mu^2; \quad var(u_i) = \sigma_u^2$ 

- For each dataset, consistent estimators of  $\sigma_{\mu}^2$  and  $\sigma_{u}^2$  are available.
- Their estimation is based on pooled OLS or FE also, we use the fact that  $\sigma_v^2 = \sigma_u^2 + \sigma_u^2$

RE estimator is a pooled OLS used on the quasi-demeaned data:

$$[y_{it} - \theta \overline{y}_i] = \beta_1 [x_{it1} - \theta \overline{x}_{i1}] + \dots + \beta_k [x_{itk} - \theta \overline{x}_{ik}] + [\mu_i - \theta \overline{a}_i + u_{it} - \theta \overline{u}_i]$$

(transformed errors follow G-M assumptions – not autocorrelated)

#### RE estimator - FGLS

$$[y_{it} - \theta \overline{y}_i] = \beta_1 [x_{it1} - \theta \overline{x}_{i1}] + \dots + \beta_k [x_{itk} - \theta \overline{x}_{ik}] + [\mu_i - \theta \overline{a}_i + u_{it} - \theta \overline{u}_i]$$

Interestingly, the FGLS equation is a general form that encompasses both FE and pooled OLS:

$$\begin{array}{cccc} \hat{\theta} \rightarrow 1 & \rightarrow & \mathrm{RE} \rightarrow & \mathrm{FE} \\ \\ \hat{\theta} \rightarrow 0 & \rightarrow & \mathrm{RE} \rightarrow & \mathrm{Pooled} \\ \end{array}$$

## RE estimator – Assumptions

- **FE.1** Functional form:  $y_{it} = \beta_1 x_{it1} + \dots + \beta_k x_{itk} + \mu_i + u_{it}, i = 1, \dots, N, t = 1, \dots, T$
- **FE.2** We have random sample from cross-sectional units.
- **FE.4**  $\forall i, t$ :  $E(u_{it} \mid X_i, \mu_i) = 0$ . [Alt.:  $corr(x_{itj}, u_{is} \mid \mu_i) = 0, \ \forall t, s$ ]
- **FE.5** Variance of idiosyncratic errors conditional on all regressors is constant:  $var(u_{it} \mid X_i, \mu_i) = var(u_{it}) = \sigma_u^2, \quad t = 1, 2, ..., T.$  [homoskedasticity]
- **FE.6** No serial correlation exists among idiosyncratic errors.  $cov(u_{it}, u_{is} \mid \mathbf{X}_i, \mu_i) = 0, \quad t \neq s$
- **FE.7** [normality of  $u_{it}$  has little actual importance for the RE estimator
- **RE.1** There are no perfect linear relationships among explanatory variables. [replaces **FE.3**]
- **RE.2** In addition to **FE.4**, the expected value of  $\mu_i$  given all regressors is constant:  $E(\mu_i \mid X_i) = \beta_0$ . [Rules out correlation between  $\mu_i$  and  $X_i$ ]
- **RE.3** In addition to **FE.5**, variance of  $\mu_i$  given all regressors is constant:  $var(\mu_i \mid \mathbf{X}_i) = \sigma_a^2$  [Homoskedasticity imposed on  $\mu_i$ ]

## RE estimator – Assumptions

Under FE.1+FE.2+RE.1+(FE.4+RE.2)

RE estimator is consistent and asymptotically normal (for fixed T as  $N \to \infty$ ).

RE standard errors and statistics are not valid unless (FE.5+RE.3) and FE.6 conditions are met.

Under FE.1-FE.2+RE.1+(FE.4+RE.2)+(FE.5+RE.3)+FE.6

RE estimator is consistent and asymptotically normal (for fixed T as  $N \to \infty$ ).

RE standard errors and statistics are valid.

RE is asymptotically efficient

- lower st.errs. than pooled OLS
  - for time-varying variables, RE estimator is more efficient than FE (FE cannot be used on time-invariant variables).

#### CRE estimator

Correlated Random Effects (CRE) estimator - a synthesis of the RE and FE approaches:

- $\mu_i$  viewed as random, yet they can be correlated with  $\boldsymbol{x}_{it}$ . Specifically, as  $\mu_i$  do not vary over time, it makes sense to allow for their correlation with the time average of  $x_{it} : \overline{x}_i = T^{-1} \sum_{t=1}^T x_{it}$
- CRE allows for incorporation of time-invariant regressors (compare to FE).
- CRE allows for convenient testing of FE vs. RE.

#### CRE estimator

CRE: The individual-specific effect  $\mu_i$  is split up into a part that is related to the time-averages of the explanatory variables and a part  $r_i$  (a time-constant unobservable) that is unrelated to the explanatory variables:

For 
$$y_{it} = \beta_1 x_{it} + \mu_i + u_{it}$$
, we assume (a single-regressor illustration):  

$$\mu_i = \alpha + \gamma \overline{x}_i + r_i, \text{ now: } cor(r_i, \overline{x}_i) = 0 \Rightarrow cor(r_i, x_{it}) = 0$$
(because  $\overline{x}_i$  is a linear function of  $x_{it}$ )

By substituting for  $\mu_i$  into the first equation, we obtain:  $y_{it} = \alpha + \beta_1 x_{it} + \gamma \overline{x}_i + r_i + u_{it}$ 

## This equation can be estimated using RE

As  $\gamma \overline{x}_i$  controls for the correlation between  $\mu_i$  and  $x_{it}$ ,  $r_i$  is uncorrelated with regressors.

## CRE estimator

CRE: 
$$y_{it} = \alpha + \beta_1 x_{it} + \gamma \overline{x}_i + r_i + u_{it}$$

CRE is a modified RE of the original equation  $y_{it} = \beta_1 x_{it} + \mu_i + u_{it}$ :

with uncorrelated random effect  $r_i$  but with the time averages as additional regressors.

The resulting CRE estimate for  $\beta$  is identical to the FE estimator.

- CRE allows for incorporation of time-invariant regressors: Besides  $\hat{\beta}_{CRE} = \hat{\beta}_{FE}$ , we can include arbitrary time invariant regressors and estimate  $\gamma_{CRE}$  values.
- CRE allows for convenient testing of FE vs. RE:

 $H_0$ :  $\gamma = 0$  can be evaluated using  $\hat{\gamma}_{CRE}$  and appropriate (HCE) standard errors against

 $H_1: \ \gamma \neq 0$ 

[RE assumes  $\gamma = 0$ : if we reject  $H_0$ , we also reject RE in favor of FE]

## Arellano-Bond estimator (dynamic panels)

#### Dynamic panel

$$y_{it} = \delta_1 y_{i,t-1} + \boldsymbol{x}'_{it} \boldsymbol{\beta} + \mu_i + u_{it}$$

... May be expanded using additional lags of the dependent variable or using lagged exogenous regressors.

#### **Nickel Bias**

- ullet Related mostly to the lagged exogenous regressors  $oldsymbol{x}$
- FEs take up some part of the dynamic effect and therefore dynamic panel data models lead to overestimated FEs and underestimated dynamic interactions.
- Whether the Nickel bias is significant in a particular model/dataset situation is an empirical question. Nevertheless, in theory this bias persists unless the number of time observations goes to infinity.
- The inclusion of additional cross-sections to the dataset would worsen the bias in most cases.

## Arellano-Bond estimator (dynamic panels)

## Arellano-Bond (AB) estimator

• The model is transformed into first differences to eliminate the individual effects:

$$\Delta y_{it} = \delta_1 \Delta y_{i,t-1} + \Delta x'_{it} \beta + \Delta u_{it},$$

- then a generalized method of moments (GMM) approach is used to produce asymptotically efficient estimates for the dynamic coefficients.
- AB approach is based on IV (we need instruments for the lagged dependent variable this is an endogenous regressor, correlated with the errors in the FD model).
- Warning: AR(2) / not AR(1) / autocorrelation in residuals of the AB-estimated model renders the AB estimator inconsistent. After using the AB estimator, always test for AR(2) autocorrelation in the residuals!

# Poolability tests

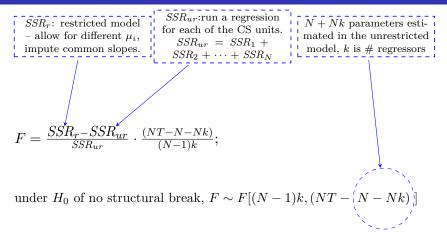

## LSDV-based test for individual intercepts

- Null hypothesis of common intercept is tested against the alternative of individual-specific intercepts.
- Common slopes are assumed (not tested)
- Unrestricted model:  $y_{it} = \beta_0 + d' \delta_0 + \beta_1 x_{it1} + \beta_2 x_{it2} + u_{it}$  where d is a vector of CSID-based dummy variables and  $\delta_0$  is a vector of regression coefficients (N-1) dummies used to avoid dummy variable trap).
- Restricted model:  $y_{it} = \beta_0 + \beta_1 x_{it1} + \beta_2 x_{it2} + u_{it}$ .
- $\bullet$  Can be implemented as an F-test for linear (zero) restrictions: Pooled regression vs LSDV model

## Chow test for identical slopes

- pooltest() from the {plm} package
- We allow for different intercepts & test for equal slopes in all CS-units
  - Estimate model separately for each CS unit.
  - Compare with "FE" model (individual intercept, common slopes on regressors) using an F-test – are the slopes identical among CS-units?
- Drawback: test cannot handle time-invariant regressors (FE; also, as the unrestricted model is estimated individually for each CS-unit, such regressors are perfectly correlated with the intercept and  $\mu_i$  elements)
- Unrestricted model:  $y_{it} = \beta_0 + \beta_{i1}x_{it} + \mu_i + u_{it}$
- Restricted model:  $y_{it} = \beta_0 + \beta_1 x_{it} + \mu_i + u_{it}$   $H_0: \beta_{11} = \beta_{21} = \dots = \beta_{N1}$  $H_1: \neg H_0$

## Chow test for identical slopes

• Alternatively, the restricted model can be amended to feature a single intercept (no  $\mu_i$  individual effects).

- plmtest(..., type="honda") from the {plm} package
- Using OLS-based ("pooling") residuals, we test the null hypothesis of redundant individual ( $\mu_i$ ) and/or time ( $\lambda_t$ ) effects.
- Individual effects:

$$y_{it} = \beta_0 + \beta_1 x_{it1} + \dots + \beta_k x_{itk} + \mu_i + \nu_{it}$$

• Time effects:

$$y_{it} = \beta_0 + \beta_1 x_{it1} + \dots + \beta_k x_{itk} + \lambda_t + \nu_{it}$$

• Twoways effects:

$$y_{it} = \beta_0 + \beta_1 x_{it1} + \dots + \beta_k x_{itk} + \mu_i + \lambda_t + \nu_{it}$$

• Note: for this LM-based tests, we only use the residuals of the pooling model (if performed on RE of FE model, corresponding pooling model is calculated internally first).

Notation follows Baltagi (2008)

#### Panel model

- $y_{it} = \alpha + \mathbf{x}'_{it}\boldsymbol{\beta} + u_{it}$  where  $u_{it} = \mu_i + \lambda_t + \nu_{it}$
- Assumptions for Honda (1985) test:
  - *i.i.d.* individual effects:  $\mu_i \sim N(0, \sigma_\mu^2)$ ;
  - *i.i.d.* time effects:  $\lambda_t \sim N(0, \sigma_{\lambda}^2)$ ;
  - *i.i.d.* idiosyncratic errors:  $\nu_{it} \sim N(0, \sigma_{\nu}^2)$ .
- Null hypotheses to be tested:
  - $H_0^{\mu}: \sigma_{\mu}^2 = 0$  (no individual effects)
  - $H_0^{\lambda}: \sigma_{\lambda}^2 = 0$  (no time effects)
  - $H_0^{\mu\lambda}$ :  $\sigma_\mu^2 = \sigma_\lambda^2 = 0$  (no individual nor time effects)

$$y_{it} = \alpha + \mathbf{x}'_{it}\boldsymbol{\beta} + u_{it}$$
 where  $u_{it} = \mu_i + \lambda_t + \nu_{it}$  Balanced panel assumed.

• Error component in stacked (matrix form):  $\mathbf{u}_i = (u_{i1}, u_{i2}, \dots, u_{iT})'$  and  $\mathbf{u} = (\mathbf{u}'_1, \mathbf{u}'_2, \dots, \mathbf{u}'_N)'$   $\mathbf{u}_i$  is  $T \times 1$  and  $\mathbf{u}$  is  $NT \times 1$ .

• In matrix form, u can be cast as:

$$oldsymbol{u} = oldsymbol{D}_{\mu}oldsymbol{\mu} + oldsymbol{D}_{\lambda}oldsymbol{\lambda} + oldsymbol{
u}$$

where

$$\boldsymbol{\mu}=(\mu_1,\ldots,\mu_N)',$$

$$\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_T)',$$

 $\boldsymbol{\nu}$  follows the structure of  $\boldsymbol{u}$ ,

 $\mathbf{D}_{\mu} = (\mathbf{I}_{N} \otimes \mathbf{\iota}_{T})$  i.e.  $\mathbf{I}_{N}$  with each row repated T-times;  $(NT \times N)$ ,

 $\boldsymbol{D}_{\lambda} = (\boldsymbol{\iota}_{N} \otimes \boldsymbol{I}_{T})$  i.e.  $\boldsymbol{I}_{T}$  stacked vertically N-times;  $(NT \times T)$ ,

note that time is the "fast index" here.

$$y_{it} = \alpha + x'_{it}\beta + u_{it}$$
 where  $u_{it} = \mu_i + \lambda_t + \nu_{it}$   
 $u = D_{\mu}\mu + D_{\lambda}\lambda + \nu$ 

- $D_{\mu}D'_{\mu} = (I_N \otimes J_T)$  i.e. block-diagonal matrix of  $J_T$ -matrices where  $J_T = \iota_T \iota'_T (J_T \text{ is a } T \times T \text{ matrix of ones}).$
- $D_{\lambda}D'_{\lambda}=(J_N\otimes I_T)$  i.e.  $N\times N$  array of  $I_T$ -matrices.
- Now, we define

$$A_r = \left[ \left( \frac{u' D_r D'_r u}{u' u} \right) - 1 \right] \text{ for } r = \mu \text{ or } r = \lambda.$$

$$y_{it} = \alpha + \mathbf{x}'_{it}\boldsymbol{\beta} + u_{it}$$
 where  $u_{it} = \mu_i + \lambda_t + \nu_{it}$  (balanced panel)

• Honda (1985) derives a uniformly most powerful LM statistics for  $H_0^{\mu}: \sigma_{\mu}^2 = 0$  against a one-sided  $H_1^{\mu}: \sigma_{\mu}^2 > 0$ :

$$\text{HO}_{\mu} = \sqrt{\frac{NT}{2(T-1)}} \ A_{\mu} \ \underset{H_0}{\longrightarrow} \ N(0,1)$$

• Similarly, for  $H_0^{\lambda}: \sigma_{\lambda}^2 = 0$  against a one-sided  $H_1^{\lambda}: \sigma_{\lambda}^2 > 0$ :

$$\mathrm{HO}_{\lambda} = \sqrt{\frac{NT}{2(T-1)}} \ A_{\lambda} \xrightarrow{H_0} N(0,1)$$

$$y_{it} = \alpha + x'_{it}\beta + u_{it}$$
 where  $u_{it} = \mu_i + \lambda_t + \nu_{it}$  (balanced panel)

• Honda (1985) provides a test statistic for  $H_0^{\mu\lambda}$ :  $\sigma_{\mu}^2 = \sigma_{\lambda}^2 = 0$  against a one-sided alternative (not derived as a uniformly most powerful LM statistics):

$$HO_{\mu\lambda} = \frac{HO_{\mu} + HO_{\lambda}}{\sqrt{2}} \rightarrow N(0,1)$$

• Honda (1985) statistics can be generalized to the unbalanced case. see e.g.: http://www.eviews.com/help/

# F-test for unobserved effects (FE-based) vs pooling model

$$y_{it} = \alpha + \mathbf{x}'_{it}\boldsymbol{\beta} + \mu_i + \lambda_t + \nu_{it}$$

- pFtest() from the {plm} package
- F-test of effects based on the comparison of "pooling" and "within" models (either "individual", "time" or "twoways" effects can be tested).
- Hence, two main arguments to the test function are plm-estimated "pooling" and "within" models.
- d.f. of the F-test depend on the number of observations and parameters restricted:
  df1 is the number of parameters restricted,
  df2 = N(T-1) (# parameters est. in the unrestricted model)
  ... remember that for each C-S observation i, we loose one d.f. as

the demeaned errors  $\ddot{\nu}_{it}$  add up to zero when summed over time.

## Hausman test: RE vs FE estimator

- phtest() from the {plm} package
- Hausman test is based on the comparison of two sets of estimates
- A classical application of the Hausman test for panel data is to compare the fixed and the random effects models:

$$H = (\hat{\beta}_{FE} - \hat{\beta}_{RE})^T [\widehat{Avar}(\hat{\beta}_{FE}) - \widehat{Avar}(\hat{\beta}_{RE})]^{-1} (\hat{\beta}_{FE} - \hat{\beta}_{RE}) \underset{H_0}{\sim} \chi^2(m)$$

where m is the number of regressors varying across i and t.

 $H_0$ :  $cov(\boldsymbol{x}_{it}, \mu_i) = 0$  ...i.e. the crucial RE assumption holds  $H_1$ : RE assumptions violated.

#### Hausman test: RE vs FE estimator

$$H = (\hat{\beta}_{FE} - \hat{\beta}_{RE})^T [\widehat{Avar}(\hat{\beta}_{FE}) - \widehat{Avar}(\hat{\beta}_{RE})]^{-1} (\hat{\beta}_{FE} - \hat{\beta}_{RE}) \underset{H_0}{\sim} \chi^2(m)$$

- If  $\hat{\beta}_{FE}$  and  $\hat{\beta}_{RE}$  do not differ too much [or when the asymptotic variances are relatively large] we do not reject  $H_0$ .
- If we may assume RE assumptions hold, both RE and FE are consistent, and RE is efficient.
- $\bullet$  For asymptotic variance estimators  $(\widehat{Avar}),$  see Wooldridge (2010).
- If we reject  $H_0$ , we need to assume that RE assumptions are violated  $\rightarrow$  RE is not consistent [we use FE].

## Wooldridge's FD-based test: FD vs FE estimator

$$y_{it} = \alpha + \boldsymbol{x}_{it}'\boldsymbol{\beta} + \mu_i + \nu_{it}$$

- pwfdtest() from the {plm} package
- Serial correlation test that can be used as a specification test to choose the most efficient estimator FD vs FE.
- If  $\nu_{it}$  are not serially correlated:
  - FE is more efficient than FD.
  - Residuals in the FD model:  $e_{it} = \nu_{it} \nu_{i,t-1}$  are correlated, with  $cor(e_{it}, e_{i,t-1}) = -0.5$ .
- Test (for models with individual effects) can be based on estimating the model  $\hat{e}_{it} = \delta \hat{e}_{i,t-1} + \eta_{it}$  based on residuals of the FD model, where we test  $H_0: \delta = -0.5$ , corresponding to the null of no serial correlation in the original (undifferenced) residuals  $\nu_{it}$ .
- If this  $H_0$  is not rejected, we would prefer FE.
- Test performs well for T asymptotics. For short panels, other serial correlation tests are available.

## Wooldridge's FD-based test: FD vs FE estimator

$$y_{it} = \alpha + \boldsymbol{x}'_{it}\boldsymbol{\beta} + \mu_i + \nu_{it}$$

- If  $\nu_{it}$  follow a random walk:
  - FD is more efficient than FE.
  - Residuals in the FE model:  $\nu_{it} = \nu_{i,t-1} + e_{it}$ .
  - Residuals in the FD model:  $e_{it} = \nu_{it} \nu_{i,t-1}$  are not serially correlated, (definition of a random walk for  $\nu_{it}$ ).
- pwfdtest(..., h0="fd")  $H_0$ : no serial correlation in FD-errors  $e_{it}$ , if not rejected, use FD.
- pwfdtest(..., h0="fe")  $H_0$ : no serial correlation in FE-errors  $\nu_{it}$ , if not rejected, use FE.
- If both rejected, whichever estimator is chosen will have serially correlated errors: use the autocorrelation-robust covariance estimators.

#### Serial correlation tests

- pwtest() Unobserved effects: "Wooldridge"-type test  $H_0: \sigma_\mu^2 = 0$  for RE model. Under  $H_0$ , average value of the scaled elements of error covariance matrix (upper/lower triangle, excluding diagonal) asymptotically follow N(0,1).

  Non-rejection of  $H_0$  favours pooled OLS, yet rejecting may be due to serial correlation (in random effects).  $H_0$  rejection does not imply existence of individual effects (may be due to serial corr.).
- pbsytest() Bera, Sosa-Escudero, Yoon (2001)
  Solution to the previous problem: three tests:
  H<sub>0</sub>: no serial correlation while controlling for random effects
  H<sub>0</sub>: no random effects (while controlling for possible ser. corr.)
  H<sub>0</sub>: no random effects & no serial correlation.
- For detailed description of both tests, see: Wooldridge, 2002 (CS and panel data analysis) https://www.jstatsoft.org/article/view/v027i02

#### General serial correlation tests

- pbgtest() Breusch-Godfrey test for panels, Mainly for RE (and pooling) models.
- Under RE assumptions of homoskedasticity and no serial correlation in the idiosyncratic error, the residuals of the quasi-demeaned regression must be spherical as well. Hence, serial correlation test (BG test) is applied to residuals in the quasi-demeaned model (may be applied to pooled OLS residuals as well).
- Technically, pbgtest() is a wrapper to bgtest() from the lmtest() package.
- With BG-test, we can test for different orders of serial correlation.
- NOT suited for FE-estimated models, for  $N \gg T$ , test is severely biased towards rejecting  $H_0$  of no ser. corr. (see next page).
- pdwtest() Durbin-Watson test for panels (...analogous).

### General serial correlation tests

$$y_{it} = \alpha + \mathbf{x}'_{it}\boldsymbol{\beta} + \mu_i + \nu_{it}$$

- pwartest() Wooldridge test for FE model and short panels.
- Under the null hypothesis of no serial correlation in the idiosyncratic residuals  $\nu_{it}$ , residuals in the FE-estimated model (time demeaned data) are correlated:

$$cor(e_{it}, e_{is}) = -1/(T-1).$$

•  $H_0$  of no serial correlation in  $\nu_{it}$  can be tested using residuals from the FE-estimated model and auxiliary regression:

$$\hat{e}_{it} = \alpha + \delta \,\hat{e}_{i,t-1} + \eta_{it}$$

By rejecting  $H_0: \delta = -1/(T-1)$ , we reject the original null hypothesis of no serial correlation in  $\nu_{it}$ .

- Test applicable to any "FE model", particularly with  $N \gg T$ .
- As T grows,  $-1/(T-1) \to 0$  and pbgtest() can be used as well.

- vcovHC() from the {plm} package, used together with functions from {lmtest}
- three types of HC/HAC covariance matrix estimators (sandwich estimator)
- Based on White's general form (for CS data):

$$\operatorname{var}(\hat{\boldsymbol{\beta}}|\mathbf{X}) = \sigma^2 [\mathbf{X}'\mathbf{X}]^{-1} [\mathbf{X}'\mathbf{\Omega}\mathbf{X}] [\mathbf{X}'\mathbf{X}]^{-1}$$

• For the panel extension of White's HC/HAC estimator, we assume no correlation between errors of different CS-units (groups) while allowing for heteroskedasticity across CS-units (and for serial correlation)

- vcovHC(..., type="white1")
- "white1" allows for general heteroskedasticity but no serial correlation, i.e.,

$$oldsymbol{\Omega}_i = egin{bmatrix} \sigma_{i1}^2 & \dots & \dots & 0 \ 0 & \sigma_{i2}^2 & & 0 \ dots & & \ddots & 0 \ 0 & \dots & \dots & \sigma_{iT}^2 \end{bmatrix}$$

and  $\Omega$  is a block-diagonal matrix of  $\Omega_i$  matrices

- "white2" is "white1" with common CS-variance:  $\Omega_i = \sigma_i^2 I_T$ .
- The counterpart to CS-related  $[X'\Omega X]$  would be:

$$\ddot{m{X}}'m{\Omega}\ddot{m{X}} = \sum_{i=1}^N \left(\ddot{m{X}}_i'm{\Omega}_i\ddot{m{X}}_i
ight)$$

where  $\ddot{\boldsymbol{X}}$  are the transformed (time-demeaned) regressors.

- vcovHC(..., type="arellano")
- "arellano" allows a fully general structure w.r.t. heteroskedasticity and serial correlation:

$$\mathbf{\Omega}_i = \begin{bmatrix} \sigma_{i1}^2 & \sigma_{i1,i2} & \dots & & & \sigma_{i1,iT} \\ \sigma_{i2,i1} & \sigma_{i2}^2 & & & & \vdots \\ \vdots & & \ddots & & & \vdots \\ \vdots & & & \sigma_{iT-1}^2 & \sigma_{iT-1,iT} \\ \sigma_{iT,i1} & \dots & \dots & \sigma_{iT,iT-1} & \sigma_{iT}^2 \end{bmatrix}$$

and  $\Omega$  is a block-diagonal matrix of  $\Omega_i$  matrices

- "arellano": consistent w.r.t. timewise correlation of the errors, but (unlike "white1", "white2"), it relies on large N asymptotics with small T (short panels).
- "white1" is inconsistent for fixed T as N grows  $\rightarrow$  use "arellano" in such case

# Cross-sectional dependence (XSD)

# Cross-sectional dependence (XSD)

- pcdtest() from the {plm} package,
- Analogous (yet distinct) to the more familiar issue of serial correlation.
- Can arise, e.g., if individuals respond to common shocks or if spatial diffusion processes are present, relating individuals in a way depending on a measure of distance (spatial models)
- If XSD is present, the consequence is, at a minimum, inefficiency of the usual estimators and invalid inference when using the standard covariance matrix.
- In {plm}, only misspeciffication tests to detect XSD are available no robust method to perform valid inference in its presence.

# Cross-sectional dependence (XSD)

• Test(s) based on on (transformations of) the product-moment correlation coefficient of a model's residuals, defined as

$$\hat{\rho}_{ij} = \frac{\sum_{t=1}^{T} \hat{u}_{it} \hat{u}_{jt}}{\left(\sum_{t=1}^{T} \hat{u}_{it}^{2}\right)^{1/2} \left(\sum_{t=1}^{T} \hat{u}_{jt}^{2}\right)^{1/2}}$$

i.e., as averages over the time dimension of pairwise correlation coefficients for each pair of CS-units.

• Pesaran's CD test (Pesaran, 2004):

$$CD = \sqrt{\frac{2}{N(N-1)}} \left( \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \sqrt{T_{ij}} \, \hat{\rho}_{ij} \right) \xrightarrow{H_0} N(0,1)$$

CD test is appropriate both in N and T-asymptotic settings. Good performance in samples of any practically relevant size and is robust to a variety of settings.
